## Model checking, hierarchical modeling and combined M-H and Gibbs

SISMID/July 14-16, 2021

Instructors: Vladimir Minin, Kari Auranen, Elizabeth Halloran

#### **Outline**

- ▶ Chain binomial model for household outbreaks of measles
  - Bayesian analysis of incompletely observed data, using data augmentation (cf. the earlier lecture and computer lab)
  - Checking the model fit through comparison of predictive data with the observed data of the final number infected
- Model extension by allowing heterogeneity across households → a hierarchical model
- ► Implementation of posterior sampling in the hierarchical model by a combined Gibbs and Metropolis algorithm

#### The observed outbreak sizes

Recall the observed data in the chain binomial model:

Chain	Chain probability	Frequency	Observed frequency	Final number infected
1	$q_i^2$	$n_1$	34	1
$1 \rightarrow 1$	$2q_i^2 p_j$	$n_{11}$	25	2
$1{\rightarrow}1{\rightarrow}1$	$2q_j p_i^2$	$n_{111}$	not observed	3
1→2	$p_j^2$	$n_{12}$	not observed	3
Total	1	N	334	

- ▶ If the final number infected is 1 or 2, the actual chain is observed
- ▶ If the final number infected is 3, the actual chain data are not observed
  - ▶ We still know that  $N_3 \equiv n_{111} + n_{12} = 275$
- ▶ In the previous analysis, we assumed  $q_j = q$  for j = 1, ..., 334, i.e., for all 334 households

#### **Prediction**

- Recall that new (predictive) data  $y^{\text{pred}}$  can be generated by drawing from their posterior predictive distribution  $f(y^{\text{pred}}|y)$
- Posterior predictive distribution because
  - conditioning on the observed data y
  - ightharpoonup predicting a future observable  $y^{\text{pred}}$
- Predictive data can be compared with the observed data to assess the fit of the model
- In this example, we compare the predictive and observed frequencies of chains 1 and 1 ightarrow 1

#### Posterior predictive distribution

▶ Denote the model parameters by  $\theta$ . Then

$$egin{aligned} f(y^{\mathsf{pred}}|y) &= \int f(y^{\mathsf{pred}}, heta|y) d heta &= \int f(y^{\mathsf{pred}}| heta, y) f( heta|y) d heta \ &= \int f(y^{\mathsf{pred}}| heta) f( heta|y) d heta \end{aligned}$$

- This means that samples from the posterior predictive distribution can be realised as follows:
  - [1] Draw an MCMC sample  $\theta_k$  from the posterior  $f(\theta|y)$  of the model parameters
  - [2] Given  $\theta_k$ , draw a sample  $y_k^{\text{pred}}$  from  $f(y^{\text{pred}}|\theta_k)$
  - [3] Repeat steps [1] and [2] K times (k = 1, ..., K)

## Model checking

► The posterior predictive distribution of the chain frequencies  $(n_1, n_{11}, n_{111}, n_{12})$  is now

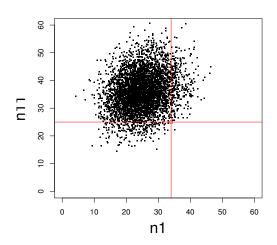

$$f(n_1^{ ext{pred}}, n_{11}^{ ext{pred}}, n_{111}^{ ext{pred}}, n_{12}^{ ext{pred}}|n_1, n_{11}, N_3) \ = \int_0^1 f(n_1^{ ext{pred}}, n_{11}^{ ext{pred}}, n_{111}^{ ext{pred}}, n_{12}^{ ext{pred}}|q) f(q|n_1, n_{11}, N_3) dq$$

- Samples from the posterior predictive distribution:
  - [1] Draw an MCMC sample  $q^{(k)}$  from the posterior  $f(q|n_1, n_{11}, N_3)$
  - [2 ] Draw a sample  $(n_1^{(k)}, n_{11}^{(k)}, n_{111}^{(k)}, n_{12}^{(k)})$  from Multinomial  $(334, (q^{(k)}, 2(q^{(k)})^2 p^{(k)}, 2q^{(k)}(p^{(k)})^2, p^{(k)}))$
  - [3] Repeat steps [1] and [2] K times (k = 1, ..., K)

## Model checking continues

- Comparison of a sample from the joint predictive posterior of  $(n_1^{\text{pred}}, n_{11}^{\text{pred}})$  with the actually observed point (34,25) reveals a poor model fit (next page)
  - ▶ The prediction shows too few chains of size 1 and too many chains  $1 \rightarrow 1$ , so the estimated escape probability appears to be too small
- ► The model did not take into account possible heterogeneity across households in the escape probability
- ► Therefore, we'll next consider a model extension through allowing such heterogeneity

## Model checking continues

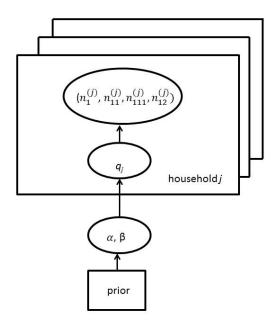

#### A hierarchical model

- ▶ In household j, let  $(n_1^{(j)}, n_{11}^{(j)}, n_{111}^{(j)}, n_{121}^{(j)})$  follow a multinomial distribution with size 1 and probability vector  $(q_i^2, 2q_i^2p_j, 2q_jp_i^2, p_i^2)$ ,  $j = 1, \ldots, 334$
- Assume that the household-specific escape probabilities  $q_j$  follow a Beta $(\alpha,\beta)$  distribution
- Assuming an uninformative joint prior\* for  $\alpha$  and  $\beta$ , the hierarchical model becomes fully defined:

$$(n_1^{(j)}, n_{11}^{(j)}, n_{111}^{(j)}, n_{12}^{(j)}) | q_j \sim \text{Multinomial}(1, (q_j^2, 2q_j^2 p_j, 2q_j p_j^2, p_j^2))$$
 $q_j | \alpha, \beta \sim \text{Beta}(\alpha, \beta)$ 
 $(\alpha, \beta) \propto (\alpha + \beta)^{-5/2}$ 

\* The odd-looking joint prior distribution for  $\alpha$  and  $\beta$  follows from assuming independent uniform prior distibutions for  $\alpha/(\alpha+\beta)$  (expectation of the Beta distribution) and  $1/(\alpha+\beta)^{-1/2}$ : see Chapter 5.3, Gelman et al.

#### A hierarchical model continues

#### The joint distribution

The joint distribution of the parameters  $\alpha$  and  $\beta$ , the household-specific escape probabilities  $q_j$  ( $j=1,\ldots,334$ ) and the chain frequencies is

$$\prod_{j=1}^{334} \left( f(n_1^{(j)}, n_{11}^{(j)}, n_{111}^{(j)}, n_{12}^{(j)} | q_j) f(q_j | \alpha, \beta) \right) f(\alpha, \beta),$$

The model unknowns are parameters  $\alpha$  and  $\beta$ , frequencies  $n_{111}^{(j)}$  for all 275 households with outbreak size 3, as well as all 334 household-specific escape probabilities  $q_j$ 

#### Sampling from the posterior cont.

- In each household, the full conditional (Beta) distribution of  $q_j^{(k)}$  depends on the current iterates of the numbers of escapes  $(e_j^{(k-1)})$  and infections  $(d_j^{(k-1)})$  in that household and the prior parameters  $\alpha^{(k-1)}$  and  $\beta^{(k-1)}$
- ► So,  $q_j^{(k)} \sim \text{Beta}(e_j^{(k-1)} + \alpha^{(k-1)}, d_j^{(k-1)} + \beta^{(k-1)})$
- ► The numbers of escapes and infections are given in the table below

Chain	Number of	Number of
	escapes $e_j^{(k-1)}$	infections $d_j^{(k-1)}$
1	2	0
$1\rightarrow 1$	2	1
$\begin{array}{c c} 1 \rightarrow 1 \\ 1 \rightarrow 1 \rightarrow 1 \end{array}$	1	2
1→2	0	2

Note that the unknown number of escapes in a household with outbreak size 3 (i.e. with either chain  $1 \rightarrow 1$  or  $1 \rightarrow 2$ ) is equal to  $n_{111}^{(j,k-1)}$ ; this is useful in implementing the sampling routine (see computer lab)

#### Sampling from the posterior

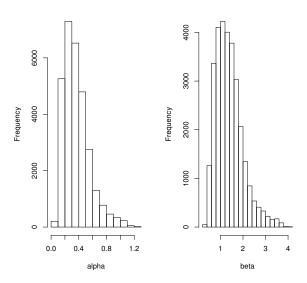

➤ A sketch of the steps in kth iteration of the sampling algorithm:

## Sampling from the posterior cont.

- lacktriangle Parameters lpha and eta require a Metropolis-Hastings step
- ▶ For example, for parameter  $\alpha$ , if the current iterate is  $\alpha^{(k-1)}$ , a new value  $\bar{\alpha}$  is first proposed (e.g.) uniformly about the current iterate (this is a symmetric proposal)
- ▶ The proposal is then accepted, i.e.,  $\alpha^{(k)} := \bar{\alpha}$ , with probability

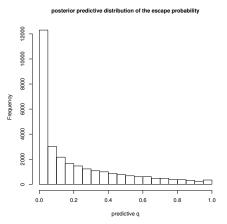

$$\begin{split} & \prod_{j=1}^{334} f(q_j^{(k)}|\bar{\alpha},\beta^{(k-1)}) f(\bar{\alpha},\beta^{(k-1)}) \\ & \min\{1,\frac{1}{334} f(q_j^{(k)}|\alpha^{(k-1)},\beta^{(k-1)}) f(\alpha^{(k-1)},\beta^{(k-1)}) \end{split}$$

#### Posterior distributions of $\alpha$ and $\beta$

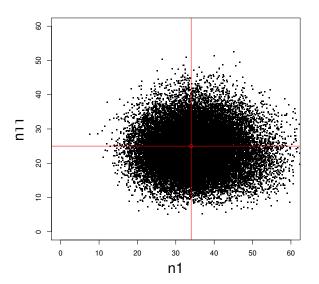

# Predictive distribution of the household-specific escape probability

Posterior predictive distribution of the household-specific escape probability,  $\int f(q_{335}|\alpha,\beta)f(\alpha,\beta|n_1,n_{11},N_3)d\alpha d\beta$ 

## Checking the hierarchical model

## An alternative approach

- ▶ In this example, it is actually possible to marginalise q<sub>j</sub> over its prior distribution
- This means calculating the chain probabilities as expectations of the probabilities given in the Table on page 3 with respect to  $\text{Beta}(\tilde{q}/z,(1-\tilde{q})/z)$ 
  - Note that the Beta distribution is now parameterised differently:  $\tilde{q} = \alpha/(\alpha + \beta)$ ,  $z = 1/(\alpha + \beta)$

Chain	Chain probability	Frequency	Observed frequency	Final number infected
1	$\tilde{q}(\tilde{q}+z)/(1+z)$	n <sub>1</sub>	34	1
$1 \rightarrow 1$	$2\tilde{p}\tilde{q}(\tilde{q}+z)/((1+z)(1+2z))$	$n_{11}$	25	2
$1 \rightarrow 1 \rightarrow 1$	$2\tilde{p}\tilde{q}(\tilde{p}+z)/((1+z)(1+2z))$	$n_{111}$	missing	3
$1\rightarrow 2$	$\tilde{p}(\tilde{p}+z)/(1+z)$	n <sub>12</sub>	missing	3

#### Alternative approach continues

▶ The following identity helps to calculate the expectations:

$$\mathsf{E}(\rho_j^u q_j^v) = \frac{\tilde{q}(\tilde{q}+z) \ldots (\tilde{q}+z(u-1)) \tilde{p}(\tilde{p}+z) \ldots (\tilde{p}+z(v-1))}{(1+z) \ldots (1+z(u+v-1))}$$

- ▶ Using the probabilities as given in the table, it is straightforward to implement a Metropolis-Hastings algorithm to draw samples from the posterior of parameters  $\tilde{q}$  and z
- ightharpoonup A suitable prior for  $\tilde{q}$  and z is of course needed
